## ABSTRACT

A nonlinear digital model of a "D" type marine boiler is developed with emphasis on water level shrink and swell phenomena. Results indicate that further specifications of the phenomena are necessary before operational values of drum level are attained.

## I. INTRODUCTION

Recent developments in control theory and practice coupled with digital electronics advances have produced increased interest in digital power plant modeling. Although conventional marine boiler modeling is not a new concept, it is still an area of increased interest due to the relative lack of analytical data. This deficiency is due primarily to the extreme environment that must be endured by sampling equipment. Advances in data collecting and processing equipment have made boiler data collection practically feasible, and in fact, nuclear steam generator development depends heavily on actual data. However, it is not economically feasible for a single manufacturer to retrofit modern data collection systems on a standard marine boiler. The majority of marine boiler models available are not attractive from the control engineer's viewpoint because of one or more of the following:

- a. The model is over-simplified to the point of being a "teapot" model.
- b. The model is completely developed and written in Laplace transforms and the state space equations are too difficult to extract.
- c. The model is over-complicated to the point of being computationally inefficient.

- d. The causes and modeling of "shrink and swell" phenomena are ignored.

This model attempts to compromise between simplification and complication while including a theory and model for shrink and swell. The model follows the path specified by Fini [1] restated below:

- a. A general D-type marine boiler model is prepared in Continuous System Modeling Program (CSMP) language.
- b. A general FORTRAN program is used to prepare the initial conditions needed by the CSMP model.
- c. The initial condition program depends only on data easily obtained from the manufacturer's technical manual and engineering handbooks.

## II. MODEL CONSIDERATIONS

### A. BOILER TYPE

The D-type boiler was chosen for modeling because of its comparative standardization among manufacturers coupled with its popularity in naval ship power plants. This particular boiler is one installed in the LHA-1 class of United States naval ships. Since D-type boilers operate under a wide range of geometry and output conditions the initial condition and model programs are designed to operate over similar ranges.

### B. MODEL NOMENCLATURE

The model nomenclature differs from reference [1] because of a need to clarify the model equations and afford readability to the actual computer programs. The following objectives were considered when developing the nomenclature.

- a. The equations must be easily read, necessitating minimum variable-definition referrals by the reader.
- b. The notation used in the model development must be the same as that used in the computer programs.

The resulting notation combines a. and b. and consists of frequently used notations for variables followed by a subscript to indicate state point location and/or time using Figure 1.

Table 1, a tabulation of general rules and examples,

should suffice to allow the reader to follow the model development.

### C. EQUATION DEVELOPMENT FORMAT

The dynamic model and initial condition programs are developed simultaneously with corresponding equations written in appropriate proximity to each other. A notation of [IC] following an equation indicates that it is an initial condition equation, while a notation of [ME] indicates a model equation. In some instances the equation applies to both programs, an indication of [IC, ME] is used to indicate this.

In as many instances as possible equations are developed directly from elementary heat transfer and fluid dynamic principles. This stems from a desire to encourage more research in this particular field and to foster a better understanding of marine boiler dynamics among students of marine engineering. The model was developed to be read and used by students with a minimum of additional research.

### D. ASSUMPTIONS

Various assumptions are made to facilitate either model simplification or program tractability. The latter are not always desirable and further research or different programming techniques may obviate the need for them. The following major assumptions are made:

1. The energy transferred to the generating tubes is distributed uniformly, i.e. "even heating" exists.

2. There is a thorough mixing of the fluid in the steam drum.
3. Steam generation occurs only in the boiling section of the screen and main bank risers.
4. All generating tubes and downcomers in a particular circuit have the average geometry.

Uniform energy transfer is assumed to facilitate model simplification and is justifiable since the generating banks are designed to optimize uniform heat transfer. Mixing of the fluid in the drum is a result of the turbulence in the drum. The third assumption results from a lack of reliable experimental data and the knowledge that D-type boilers are natural circulation boilers relying on a density difference in the circulation loop to promote flow. Steam production outside of the generating banks would decrease the density difference, thus inhibiting natural circulation. The geometry assumption is necessitated by model simplification.

### III. MODEL DEVELOPMENT

#### A. GENERAL

The boiler is developed from control volumes for which the appropriate equations for energy transfer and storage rates are written. The initial condition equations are generated by setting the rate ( $d/dt$ ) terms equal to zero and solving for the desired variables.

The model is developed with three different elements:

1. Furnace-side heat transfer
2. Water-side heat transfer
3. Water-side circulation

#### B. FURNACE-SIDE HEAT TRANSFER

The gas flow path can be followed on Figure 1 where it is represented by the dashed line. The fuel and air mixture enters the furnace at state point Q where radiation heat transfer occurs to the screen riser tube metal. The flue gas then leaves the furnace and exchanges heat via convection with the superheater (state point R-S), main bank riser tubes (state points S-T), and economizer (state points T-U) in that order.

At state point Q the fuel-to-air ratio and fuel and air temperatures are relatively constant. This allows the sensible heat of the fuel and air to be lumped. The mass flow rate into the furnace is the sum of the air flow and fuel flow.

$$M_{QQ} = M_{FQQ} + M_{AQQ} \quad [ME]$$

The initial values of fuel and air flow at a specified operating point are known. Therefore, the corresponding initial condition equation is:

$$M_{QQ\phi} = M_{FQQ\phi} + M_{AQQ\phi} \quad [IC]$$

The mass flow rates through the remaining sections of the boiler are the same.

$$M_{QQ} = M_{RR} = M_{SS} = M_{TT} = M_{UU} \quad [ME]$$

$$M_{QQ\phi} = M_{RR\phi} = M_{SS\phi} = M_{TT\phi} = M_{UU\phi} \quad [IC]$$

The total heat supplied to the boiler can be written as the product of the mass flow rate of fuel and the "lumped" fuel heating value.

$$Q_Q = M_{FQQ} * F_{HV} \quad [ME]$$

At a specific operating point the heat released to the furnace is available from the technical manual as is the furnace volume. The total heat input at steady state is the product of these two.

$$Q_{Q\phi} = Q_{TOT\phi} * F_{URVOL} \quad [IC]$$

This allows the computation of the fuel heating value.

$$F_{HV} = Q_{Q\phi} / M_{FQQ\phi} \quad [IC]$$

# 1. Furnace to Screen Risers

The heat transfer to the furnace screen tubes occurs primarily through radiation, i.e.

$$Q = \sigma A (T_{RR}^4 - T_{VV}^4)$$

which is the Stefan-Boltzmann law<sup>1</sup> where  $\sigma$  is the Stefan-Boltzmann constant defined as:

$$\sigma = 2.8567 \times 10^{-11} \frac{\text{BTU}}{\text{Sec-ft}^2-\text{°R}^4}$$

Therefore the heat transfer to the furnace screen can be written

$$Q1 = \text{SIGMAA} * ((T_{RR} + 460 \phi \phi) * * 4 \phi - (T_{VV} + 460 \phi \phi) * * 4 \phi) \quad [\text{ME}]$$

where

$$\text{SIGMAA} \equiv \sigma * A$$

At a given operating point, technical manual values are specified for the furnace heat absorption rate and the area of the radiant heat absorbing surface of the furnace screen. The product of these two yields the steady state heat transfer rate which in turn can be used to compute SIGMAA.

---

<sup>1</sup>This equation assumes that all the radiation from the combustion flame strikes the screen tubes, and both the flame and the tubes behave as black surfaces.

$$Q1\phi = QFURAB * ARAD \quad [IC]$$

$$SIGMAA = Q1\phi / ((TRR\phi + 46\phi.\phi) * * 4.\phi - (TVV\phi + 46\phi.\phi) * * 4.\phi)$$

An energy balance equation for the mass of flue gases in the furnace region can be written in the form

$$\frac{d}{dt} (m c_p T) = \text{total energy supplied} - \text{energy transferred to screen tubes} - \text{energy of gas leaving furnace region}$$

or

$$\frac{d}{dt} (\text{MASSQR} * CQR * TRR) = QQ - Q1 - MRR * CQR * (TRR - TAMB)$$

Note: TRR-TAMB is the absolute temperature. At steady state the rate terms are equal to zero. Values of total heat supplied to the boiler, heat transfer rate to the screen tubes, total flue gas flow rate, and flue gas temperature are available from previous equations. This allows the specific heat of the flue gas in the furnace region to be computed.

$$CQR = (QQ\phi - Q1\phi) / (MRR\phi * (TQR\phi - TAMB)) \quad [IC]$$

During a transient, the density of the flue gas in the furnace and the specific heat of the furnace flue gas can be regarded as constants near a steady state operating point. The dynamic equation can be written as

$$DTRR = \frac{(QQ - Q1 - MRR * CQR * (TRR - TAMB))}{(MASSQR * CQR)} \quad [ME]$$

where

$$MASSQR = RFLUE * FURVOL \quad [IC]$$

Thus,

$$TRR = \int_{t_1}^{t_2} DTRR + TRR\phi$$

or in CSMP-III language

$$TRR = INTGR1(TRR\phi, DTRR) \quad [ME]$$

The value for TRR0 is available from the technical manual.

## 2. Flue Gas to Superheater

For the remaining tube banks heat transfer occurs primarily through convection. The energy given up by the flue gas in flowing over the tube surfaces is represented by the general equation

$$\begin{array}{lll} \text{energy} & = & \text{mass flow} * \text{specific} \\ \text{given up} & \text{rate of} & \text{heat of} \\ & \text{flue gas} & \text{flue gas} \end{array}$$

\* change in temperature of the gas

i.e.

$$q = \dot{m} C_p \Delta T$$

At steady state, the energy transferred to the superheater tubes from the gas must equal the energy transferred from the tubes to the steam.

$$Q_{3\phi} = Q_{4\phi} \quad [IC]$$

The steady state values for superheater inlet and outlet steam temperature and pressure are specified by the technical manual along with the superheated steam mass flow rate. This allows the direct computation of  $Q_{40}$  and  $Q_{30}$ .

$$Q_{4\phi} = M_{MM\phi} * (H_{NN\phi} - H_{MM\phi}) \quad [IC]$$

$H_{MM0}$  is the enthalpy of saturated steam corresponding to drum pressure, computed with curve fitted equations [2].  $H_{NN0}$  is available directly from the technical manual. The specific heat of the flue gas in the superheater region can now be computed.

$$CRS = Q_{3\phi} / (M_{RR\phi} * (T_{RR\phi} - T_{SS\phi})) \quad [IC]$$

Thus the dynamic equation for heat transferred from the flue gas to the tube metal is written:

$$Q_3 = M_{RR} * CRS * (T_{RR} - T_{SS}) \quad [ME]$$

The heat transferred to the tubes via convection may also be represented by the Grimson correlation [3] which states that for cross flow over tubes;

$$\frac{hd}{k_f} = C \left( \frac{u_\infty d}{\nu_f} \right)^n Pr^{1/3}$$

where

$u_\infty$  = velocity

$d$  = tube diameter

$C$  = constant

$Pr$  = Prandtl number

Since  $h$  can also be written

$$h = q / A \Delta T$$

then

$$q = AC \left( \frac{u_\infty d}{\nu_f} \right)^n Pr^{1/3} \Delta T \left( \frac{k_f}{d} \right)$$

also

$$u_\infty = \frac{\dot{m}}{\rho A}$$

leading to the general equation

$$q = AC \left( \frac{d}{\nu_f \rho A} \right)^n Pr^{1/3} \dot{m}^n \Delta T \left( \frac{k_f}{d} \right)$$

Around a particular steady state operating point the physical properties can be regarded as a constant and the physical dimensions are constant, i.e.

$$Ac \left( \frac{d}{v_f \rho A} \right)^n Pr^{1/3} = \text{constant}$$

which implies

$$q = (\text{constant}) * \dot{m}^n \Delta T$$

For flow over tube banks with differing rows of tubes and differing tube geometries the constant (n) varies little and the average is approximately .6 [3]. Therefore, in the case of the superheater and main bank riser tubes, the correlation is used in the form

$$q = C \dot{m}^{.6} \Delta T$$

or for the superheater

$$Q3 = KRS * MRR * * .6 * (TRS - TWW)$$

where TRS is the average flue gas temperature

$$TRS = (TRR + TSS) / 2.0$$

Since the steady state values for Q30, MRR0, TRR0, TSS0, and TWW0 are given by the technical manual the constant KRS can be calculated.

$$KRS = Q30 / (MRR0 * * .6 * (TRR0 - TWW0)) [IC]$$

To provide the dynamic solution of superheater flue gas outlet temperature, the two transient equations for the flue gas to superheater tube metal heat transfer are equated resulting in

$$\frac{TRS - TWW}{TRR - TSS} = MRR \cdot^4 * CRS / KRS$$

where

$$TRS = (TRR + TSS) / 2.0$$

Solving the above for TSS gives

$$TSS = (TRR * (PHI1 - 1) + 2 * TWW) / (PHI1 + 1) \quad [ME]$$

where

$$PHI1 = 2 * MRR * * .4 * CRS / KRS \quad [ME]$$

### 3. Flue Gas to Main Bank Risers

The equations for the flue gas to tube metal energy transfer in the main bank are derived similarly. For the equation involving flue gas specific heat;

$$Q5 = MSS * CST * (TSS - TTT) \quad [ME]$$

The Grimson correlation equation for the main bank risers is

$$Q5 = KST * MSS * * 0.6 * (TST - TYY)$$

where

$$T_{ST} = (T_{SS} + T_{TT}) / 2.0$$

By equating these two equations as was done with the superheater the flue gas temperature leaving the main bank can be written

$$T_{TT} = (T_{SS} * (PHI2 - 1) + 2 * T_{YY}) / (PHI2 + 1) \text{ [ME]}$$

where

$$PHI2 = 2 * M_{SS} * 0.4 * C_{ST} / K_{ST} \text{ [ME]}$$

The steady state heat transfer is computed differently than that for the superheater. Since the steady state heat transfer to the screen bank has been computed, the energy transferred to the main bank is the difference between the total energy transferred and the desuperheater and screen bank energy transfer. At steady state the mass flow rate of steam out of the boiler is equal to the mass flow rate of feed in the boiler and the total energy transferred is the mass flow rate multiplied by the enthalpy change between the outgoing steam and incoming feedwater. Thus, the steady state energy transfer equation for the main bank is

$$Q_{60} = M_{MM} * (H_{MM} - H_{00}) - Q_{20} - Q_{990} \text{ [IC]}$$

$Q_{990}$  is computed in the water side heat transfer section.

Since  $Q_{50} = Q_{60}$  at steady state the heat transfer coefficient  $K_{ST}$  and the specific heat  $C_{ST}$  can be computed.

$$K_{ST} = Q_{50} / (M_{SS} * 0.6 * (T_{ST} - T_{YY})) \text{ [IC]}$$

$$C_{ST} = Q_{50} / (M_{SS} * (T_{SS} - T_{TT})) \text{ [IC]}$$

#### 4. Flue Gas to Economizer

The economizer tubes differ from the generating and superheater tubes in that they are finned. A reasonable finned tube heat transfer correlation was developed by Weirmann, et al. [4]

$$j = \frac{h P_r^{2/3}}{C_p G_{\max}}$$

$G_{\max} \equiv$  maximum mass flow rate

$j \equiv$  correlation constant

$C_p \equiv$  specific heat of flue gas

Since  $h = \frac{q}{A \Delta T}$  the above

correlation can be written

$$q = \frac{j A \Delta T C_p G_{\max}}{P_r^{2/3}}$$

$G_{\max}$  is a function of mass flow rate into the tube bank and tube bank geometry. Similar to the case of the Grimson coefficient used for the superheater and main bank tubes the physical and geometric properties are considered constant leading to the use of the correlation in the form

$$q = C \dot{m} \Delta T$$

Therefore, for the economizer the equation is

$$Q7 = K_{TU} * M_{TT} * (T_{Tu} - T_{XX})$$

where

$$T_{Tu} = \frac{T_{TT} + T_{uu}}{2.0}$$

Paralleling the superheater and main bank, the heat transfer may also be written

$$Q7 = M_{TT} * C_{Tu} * (T_{TT} - T_{uu}) \quad [ME]$$

The steady state equation development follows that of the superheater and main bank sections and is not repeated here.

The equations are:

$$Q8\phi = M_{AA\phi} * (H_{BB\phi} - H_{AA\phi}) \quad [IC]$$

$$Q7\phi = Q8\phi \quad [IC]$$

$$C_{Tu} = Q7\phi / (M_{TT\phi} * (T_{TT\phi} - T_{uu\phi})) \quad [IC]$$

$$K_{Tu} = Q7\phi / (M_{TT\phi} * (T_{Tu\phi} - T_{XX\phi})) \quad [IC]$$

$$T_{Tu\phi} = (T_{TT\phi} + T_{uu\phi}) / 2.0 \quad [IC]$$

Knowing the values for  $K_{Tu}$  and  $C_{Tu}$  developed by the initial condition program allows the solution of the flue gas outlet temperature in the transient analysis. Thus,

$$[ME] \quad T_{uu} = (T_{TT} * (PHI3 - 1.0) + 2.0 * T_{XX}) / (PHI3 + 1.0)$$

$$[ME] \quad PHI3 = 2.0 * C_{Tu} / K_{Tu}$$

## C. WATER SIDE HEAT TRANSFER

### 1. Risers

The heat supplied to the riser banks is used both in the boiling and nonboiling length of the tube; however the assumption is made here that the heat transfer is all under fully developed flow boiling conditions. Since the nonboiling length of the risers is relatively small, little error is produced. For fully developed nucleate flow boiling, Levy [5] suggests the equation

$$Q = \frac{A P_{sat}^{4/3}}{1.782 \times 10^6} \Delta T_{sat}^3 \frac{\text{BTU}}{\text{sec-ft}^2}$$

By lumping the constant area and denominator the riser equations can be written in the forms

$$Q = C * P_{SAT}^{4/3} * \Delta T_{SAT}^3$$

Therefore, the two riser equations are

$$Q_2 = K_V * P_{SAT} * (4.0/3.0) * (T_{VV} - T_{SAT}) * 3.0 \text{ [ME]}$$

and

$$Q_6 = K_Y * P_{SAT} * (4.0/3.0) * (T_{YY} - T_{SAT}) * 3.0 \text{ [ME]}$$

for the screen and main bank respectively. A simple energy balance on the tube metal yields the metal temperatures, i.e.,

$$\text{mass} * C_p * \frac{dT}{dt} = q_{in} - q_{out}$$

The equations for screen and main bank metal temperatures are:

$$DTVV = (Q1 - Q2) / (MASSV * CPV) \quad [ME]$$

$$TVV = \text{INTGRL}(TVV\phi, DTVV) \quad [ME]$$

$$DTYY = (Q5 - Q6) / (MASSY * CPY) \quad [ME]$$

$$TYY = \text{INTGRL}(TYY\phi, DTYY) \quad [ME]$$

The heat transfer coefficient KY can be computed directly from tube geometrical data available in the technical manual;

$$KY = \text{AREAMB} / 1.782E \phi 6 \quad [IC]$$

Since  $Q10 = Q20$  at steady state, the dynamic equation for  $Q20$  can be solved in a steady state situation for KV,

$$[IC] \quad KV = Q1\phi / (PSAT^{**} (4/3) * (TVV\phi - TSAT)^{**} 3.\phi)$$

$Q60$  was computed in Section III-B.3. This allows the calculation of the initial main bank riser tube metal temperature,

$$[IC] \quad TYY\phi = (Q6\phi / (KY * PSAT^{**} (4/3)))^{**} (1/3) + TSAT$$

In the case of the screen risers, the initial tube metal temperature is available from the technical manual and the initial heat transfer rate has been previously calculated. This allows the calculation of the screen riser steamside heat transfer coefficient,

$$[IC] \quad KV = Q1\phi / (PSAT^{**} (4.\phi / 3.\phi) * (TVV\phi - TSAT)^{**} 3.\phi)$$

## 2. Desuperheater

The Dittus-Boelter correlation [6] is used to compute the heat transfer rate from the steam to the desuperheater tubes. This correlation in its basic format is

$$Nu = .\phi 23 Re^{0.8} Pr^n$$

where

Nu => Nusselt number

Re => Reynolds number

Pr => Prandtl number

n => .3 (for cooling fluid)

When the appropriate variables and constants are substituted for the dimensionless numbers, the Dittus-Boelter correlation can be written

$$Q = K \dot{m}^{.8} \Delta T$$

where the constant K is defined as:

$$K = .\phi 23 * \frac{\text{thermal conductivity} * \text{heat transfer area}}{\text{tube diameter}}$$

$$* \left( \frac{4}{\pi * \text{tube diameter} * \text{viscosity} * \text{nr of tubes}} \right)^{.8}$$

$$* Pr^{.3}$$

and  $\Delta T$  is the log-mean-temperature difference (LMTD).

Thus, for the desuperheater, the equation is

$$Q_9 = KNP * MNN * .8 * LMTDNP$$

KNP can be computed directly. Thus,

$$KNP = ((.023 * THCONN) / DNP) * (4.0 / (PI * DNP * VISCON * NTUBDS)) * .8 * PRAN * .3 * AREAS \quad [IC]$$

The energy given up by the steam to the tubes may also be written in terms of steam specific heat, flow rate, and temperature difference.

$$Q_9 = CNP * MNN * (TNN - TPP) \quad [ME]$$

Similarly since the heat transfer to the water in the drum is totally by convection;

$$Q_{99} = KZ * (TZZ - THH) \quad [ME]$$

For initial condition calculations THH is considered to be equal to TSAT. Therefore

$$KZ = Q_{99} / (TZZ - TSAT) \quad [IC]$$

The desuperheater outlet temperature is solved by equating the two dynamic equations for  $Q_9$  and solving for the desired outlet temperature.

$$TPP = (TNN - TZZ) / (\exp(KNP / (CNP * MNN * .2))) + TZZ \quad [ME]$$

The instantaneous desuperheater tube metal temperature is obtained by an energy balance on the tube metal similar to that for the riser tube metal.

$$\text{mass} * C_p * \frac{dT}{dt} = q_{in} - q_{out}$$

Solving the appropriate equation for  $dT/dt$  results in

$$DTZZ = (Q9 - Q99) / (\text{MASSZ} * CPZ) \quad [ME]$$

$$TZZ = \text{INTGR}(TZZ\phi, DTZZ) \quad [ME]$$

The specific heat of the steam in the desuperheater (CNP) may be calculated using the known steady state values for desuperheated steam flow rate and the desuperheater inlet and outlet temperatures and pressures.

$$Q9\phi = MNN\phi * (HNN\phi - HPP\phi) \quad [IC]$$

$$CNP = Q9\phi / (MNN\phi * (TNN\phi - TPP\phi)) \quad [IC]$$

With the value of  $Q90$  computed the initial log-mean-temperature difference can be calculated.

$$LMTDNP = Q9\phi / (KNP * MNN\phi * \phi.8)$$

The log-mean-temperature difference is a function of steam temperature in, tube metal temperature, and steam temperature out; therefore the initial tube metal temperature may be calculated.

$$T_{\text{RZ}}\phi = (T_{\text{NN}}\phi - \text{EXP00S} * T_{\text{PP}}\phi) / (1.\phi - \text{EXP00S}) \quad [\text{IC}]$$

$$\text{EXP00S} = \exp((T_{\text{NN}}\phi - T_{\text{PP}}\phi) / \text{LMT0NP}) \quad [\text{IC}]$$

### 3. Economizer

Paralleling the desuperheater development the Dittus-Boelter correlation is used to relate the heat transfer from the tube metal to the feedwater. Thus,

$$\text{Nu} = .\phi 23 \text{Re}^{.8} \text{Pr}^n$$

the only difference being that  $n$  is now .4 vice .3 because the fluid is now being heated. The appropriate constants are again lumped yielding

$$Q_8 = KX * \text{MAA} * \phi .8 * \text{LMTDAB}$$

An energy balance on the water gives the heat absorbed in two other forms;

$$Q_8 = \text{MAA} * (H_{\text{BB}} - H_{\text{AA}})$$

$$Q_8 = \text{MAA} * C_{\text{AB}} * (T_{\text{BB}} - T_{\text{AA}}) \quad [\text{ME}]$$

At the specified operating point the inlet and outlet conditions of the economizer as well as the mass flow rate are given, allowing the computation of the steady state heat transfer.

$$Q_8\phi = \text{MAA}\phi * (H_{\text{BB}}\phi - H_{\text{AA}}\phi) \quad [\text{IC}]$$

The heat transfer coefficient KX is computed directly.

$$KX = ((.023 * THCONA) / DAB) * (4.0 / (PI * DAB * VISCOA * NTUBEC)) * .8 * PRAA * .4 * AREAEC \quad [IC]$$

This permits the solution of the steady state log-mean-temperature difference.

$$LMTDAB = Q80 / (KX * MAA * .8) \quad [IC]$$

Following the identical path delineated for the desuperheater, the tube metal initial temperature can be computed.

$$TXX0 = (TAA0 - TBB0 * EXPOEC) / (1.0 - EXPOEC) \quad [IC]$$

$$EXPOEC = EXP((TBB0 - TAA0) / LMTDAB) \quad [IC]$$

An energy balance on the economizer tube metal yields its instantaneous temperature.

$$DTXX = (Q8 - Q7) / (MASSX * CPX) \quad [ME]$$

$$TXX = INTGRL(TXX0, DTXX) \quad [ME]$$

By equating the formulations for Q8 involving LMTD and specific heat, the economizer outlet temperature may be calculated.

$$TBB = (TAA - TXX) / (EXP(KX / (CAB * MAA * .2))) + TXX \quad [ME]$$

The specific heat of the feedwater in the economizer is calculated at steady state using the computed value of steady state heat transfer and the given mass flow rates and inlet and outlet temperatures.

$$C_{AB} = Q_{8\phi} / (M_{AA\phi} * (T_{BB\phi} - T_{AA\phi})) \quad [IC]$$

#### 4. Superheater

The development of the superheater equations follows that of the desuperheater and economizer and for that reason the development will not be repeated. The equations are listed below.

$$Q_4 = C_{MN} * M_{MM} * (T_{NN} - T_{MM}) \quad [ME]$$

$$Q_{4\phi} = M_{MM\phi} * (H_{NN\phi} - H_{MM\phi}) \quad [IC]$$

$$C_{MN} = Q_{4\phi} / (M_{MM\phi} * (T_{NN\phi} - T_{MM\phi})) \quad [IC]$$

The initial superheater log-mean-temperature difference is computed directly allowing the subsequent calculation of the tube-metal-to-steam heat transfer coefficient used in the Dittus-Boelter equation.

$$LMT_{DMN} = (T_{NN\phi} - T_{MM\phi}) / (A \log ((T_{WW\phi} - T_{MM\phi}) / (T_{WW\phi} - T_{NN\phi}))) \quad [IC]$$

$$K_W = Q_{4\phi} / (m_{MM\phi} * * \phi.8 * LMT_{DMN}) \quad [IC]$$

An energy balance on the tube metal yields the instantaneous tube metal temperature, the initial tube metal temperature being available from the technical manual.

$$DTWW = (Q3 - Q4) / (MASSW * CPW) \quad [ME]$$

$$TWW = INTGRL (TWW\phi, DTWW) \quad [ME]$$

The superheater outlet temperature can now be calculated.

$$TNN = (TMM - TWW) / (EXP (KW / (CMN * MNN * \phi.2))) + TWW \quad [ME]$$

#### D. WATER-SIDE CIRCULATION

##### 1. General

The water/steam side circulation equations are by far the most difficult to visualize and codify. These equations must be accurate in order to predict phenomena such as shrink and swell while appropriate assumptions and simplifications must be made in order to make the equations tractable.

As can be seen in Figure 1, the feedwater enters the economizer at state point A, passes through the economizer to the steam drum where it becomes part of the water volume. The liquid leaves the drum via the downcomers, both main bank and screen at state points G and C respectively. The main bank downcomer delivers its liquid to the main bank risers via the water drum, and the main bank risers deliver the fluid to the steam separators. The flow through the screen risers is the same with the exception that there is no water drum in this circuit. The steam separators separate the majority of

the water from the steam leaving the drum at state point M and the majority of the steam from the water being discharged back into the drum liquid. The steam, with a negligible amount of water passes through the superheater via state point M-N. At the outlet of the superheater the steam leaving at path III is used for "main" steam; that leaving via path II travels to the desuperheater where it is cooled, then leaves via state point P and is used for auxiliary steam.

The water leaving the separators with a small amount of entrained vapor is mixed with the incoming feed water and forms a "foaming" vapor/liquid mass in the bottom half of the drum. The liquid from this mass leaves via the downcomers and is circulated through the loop.

## 2. Downcomer Pressure Drop

A closer look at the downcomer flow is necessary to justify assumptions that are made in the development of the pressure-drop equations.

Circulation ratio is defined as the ratio of the total weight of steam liberated to the drum [7]. For a 600 pound marine boiler this circulation ratio is on the order of 20:1 [7 and 8]. This implies that for every 21 pounds of liquid flowing down the downcomers, 20 pounds of it has already traveled up the riser and is at saturation temperature. Therefore, assuming the downcomers are perfectly insulated, it is reasonable to assume that the downcomer liquid is at or very near saturation temperature.

The momentum equation for the downcomers may be written:

$$\begin{aligned}
 & \text{pressure at top} - \text{pressure at bottom} \\
 = & \text{frictional loss} - \text{gravitational head} \\
 & + \text{entrance loss} \quad + \text{bend loss} \\
 & + \text{exit loss} \quad + \text{inertia force}
 \end{aligned}$$

The inertia force term may be considered negligible [9].

This is the quasistatic approximation which basically states that pressure waves move much more rapidly through the system than the important time constants. This is mathematically equivalent to the elimination of a large negative eigenvalue. This quasistatic approximation is only good for on-line transients and does not apply for extremely large discontinuities which would result in the boiler being taken out of operation, (e.g., a ruptured tube). Therefore the downcomer momentum equation can be written:

$$\begin{aligned}
 & \text{pressure at top} - \text{pressure at bottom} \\
 = & \left( \text{friction factor} * \text{downcomer length} \right. \\
 & \div \text{downcomer diameter} + \text{entrance factor} \\
 & + \text{bend factor} \quad + \text{exit factor} \left. \right) \\
 * & \left( \text{downcomer mass flow rate} \right)^2 \div \left( 2 * \left( \text{downcomer} \right. \right. \\
 & \left. \left. \text{cross sectional area} \right)^2 * \text{density of fluid} \right. \\
 & \left. \text{in downcomer} * g_c \right) - \text{density of fluid in} \\
 & \text{downcomer} * \text{gravitational acceleration} * \\
 & \text{height of downcomer} \div g_c
 \end{aligned}$$

In the model notation

$$P_{CPD} = (F_{CD} * L_{CD} / D_{CD} + ENTR_{CD} + BEND_{CD} + EXIT_{CD}) * M_{CC} * 2. \phi / (2. \phi * A_{CD} * 2. \phi * RHO_{CD} * G_C) - RHO_{CD} * G * Z_{CD} / G_C$$

$$P_{GPH} = (F_{GH} * L_{GH} / D_{GH} + ENTR_{GH} + BEND_{GH} + EXIT_{GH}) * M_{GG} * 2. \phi / (2. \phi * A_{GH} * 2. \phi * RHO_{GH} * G_C) - RHO_{GH} * G * Z_{GH} / G_C$$

for the screen and main bank downcomers respectively.  $F_{CD}$  and  $F_{GH}$  are friction factors of the form

$$f = 1 / (1.74 - 2 \log (R / K_S))$$

where  $R$  is the pipe radius and  $K_S$  is the relative sand roughness [11].

$$F_{CD} = 1. \phi / (1.74 - 2. \phi * A \log_{10} (K_{SCD})) \quad [IC, ME]$$

$$F_{GH} = 1. \phi / (1.74 - 2. \phi * A \log_{10} (K_{SGH})) \quad [IC, ME]$$

### 3. Riser Pressure Drop

The momentum equation for the riser boiling section must take two phase flow effects into account because the flow in the boiling section is not homogeneous. Thus, there is a relative velocity between the liquid and vapor phases here. The steam separators are included in the riser length. However,

the effective length of the separators and thus the pressure drop are considered negligible because of a general lack of information concerning these items.

The pressure drop due to single phase or homogeneous flow in the nonboiling riser section can be written

$$\Delta P_{SPF} = \Delta P_{\text{acceleration}} + \Delta P_{\text{friction}} + \Delta P_{\text{gravity}}$$

$$\Delta P_{\text{acceleration}} = \frac{\dot{m}^2}{g_c * A^2} * \frac{(\rho_{\text{out}} - \rho_{\text{in}})}{\rho_{\text{out}} * \rho_{\text{in}}}$$

$$\Delta P_{\text{friction}} = \frac{4 * f * \text{length} * \dot{m}^2}{g_c * D * (\rho_{\text{out}} + \rho_{\text{in}}) * A^2}$$

$$\Delta P_{\text{gravity}} = \frac{g * \text{height} * (\rho_{\text{out}} + \rho_{\text{in}})}{2 * g_c}$$

Experiments conducted by Babcock and Wilcox [10] indicate that these homogeneous flow pressure drops may be modified to give the appropriate two phase flow pressure drops using correction factors that are functions of outlet quality and operating pressure. The two phase flow pressure drop can be written;

$$\begin{aligned} \Delta P_{TPF} = & \Delta P_{\text{acceleration}} * r_{\text{acceleration}} \\ & + \Delta P_{\text{friction}} * r_{\text{friction}} \\ & + \Delta P_{\text{gravity}} * r_{\text{gravity}} \end{aligned}$$

where the  $r$  terms are two phase flow correction factors available by using curve fits of the data from reference [10].

The form of these r terms become:

$$R_{GRAVE} = 24.794 * X_{FF\phi} * * 2.\phi - 6.5\phi66 * X_{FF\phi} + .9776 \quad [Ic]$$

$$R_{GRAVK} = 24.794 * X_{LL\phi} * * 2.\phi - 6.5\phi66 * X_{LL\phi} + .9776 \quad [Ic]$$

$$R_{ACLE} = 15.4564 * X_{FF\phi} * * 2.\phi + 18.4944 * X_{FF\phi} - .\phi\phi\phi\phi7 \quad [Ic]$$

$$R_{ACLJ} = 15.4564 * X_{LL\phi} * * 2.\phi + 18.4944 * X_{LL\phi} - .\phi\phi\phi\phi7 \quad [Ic]$$

$$R_{FRICE} = -34.\phi822 * X_{FF\phi} * * 2.\phi + 23.7164 * X_{FF\phi} + .8734 \quad [Ic]$$

$$R_{FRICK} = -34.\phi822 * X_{LL\phi} * * 2.\phi + 23.7164 * X_{LL\phi} + .8734 \quad [Ic]$$

Therefore, in the boiling region of the riser

$$\Delta P_{TPF} = \frac{\dot{m}^2 r_{acl}}{g_c \rho_{in} A^2} + \frac{2 f (\text{boiling length}) \dot{m}^2 r_{fric}}{g_c (\text{diameter}) \rho_{in} A^2} + \frac{g (\text{height of boiling region}) \rho_{in} r_{grav}}{g_c}$$

The total pressure drop across the length of the riser is;

$$\Delta P = \Delta P_{SPF} + \Delta P_{TPF}$$

In model notation the equations are

$$\begin{aligned}
 POPF = & (MOD * * 2.\phi * (RHOEE - RHODD)) / (GC * RHOEE * \\
 & RHODD * ADE * * 2.\phi) + (4.\phi * FDE * LDE \\
 & * MOD * * 2.\phi) / (GC * DDE * (RHODD + \\
 & RHOEE) * ADE * * 2.\phi) + (G * ZDE * (RHODD \\
 & + RHOEE)) / (GC * 2.\phi) + (MOD * * 2.\phi * \\
 & RACLE) / (GC * RHOEE * AEF * * 2.\phi) + \\
 & (2.\phi * FEF * LEF * MOD * * 2.\phi * RFRICE) / \\
 & (GC * DEF * RHOEE * AEF * * 2.\phi) + \\
 & (G * ZEF * RHOEE * RGRAVE) / GC
 \end{aligned}$$

$$\begin{aligned}
 PJPL = & (MJT * * 2.\phi * (RHOKK - RHOTJ)) / GC * RHOKK * \\
 & RHOTJ * AJK * * 2.\phi) + (4.\phi * FJK * MJT * * \\
 & 2.\phi * LJK) / (GC * DJK * (RHOTJ + RHOKK) * \\
 & AJK * * 2.\phi + G * ZJK * (RHOTJ + RHOKK) / \\
 & (GC * 2.\phi) + (MJT * * 2.\phi * RACK) / \\
 & (GC * RHOKK * AKL * * 2.\phi) + (2.\phi * \\
 & FKL * LKL * MJT * * 2.\phi * RFRICK) / \\
 & (GC * DKL * RHOKK * AKL * * 2.\phi) + \\
 & (G * ZKL * RHOKK * RGRAVK) / GC
 \end{aligned}$$

The friction factors are in the same form as those for the downcomers

$$\begin{aligned} FDE &= 1. \phi / (1.74 - 2. \phi * A \log 1 \phi (KSDE)) & [IC] \\ FEF &= 1. \phi / (1.74 - 2. \phi * A \log 1 \phi (KSEF)) & [IC] \\ FJK &= 1. \phi / (1.74 - 2. \phi * A \log 1 \phi (KSJK)) & [IC] \\ FKL &= 1. \phi / (1.74 - 2. \phi * A \log 1 \phi (KSKL)) & [IC] \end{aligned}$$

At a specified steady state operating point the pressure drop across the downcomers must equal the pressure drop across the risers and the downcomer flow rate must equal the riser flow rate. Therefore by equating the appropriate pressure drop equations and solving the resultant relation for the flow rates, the initial flow rates may be computed as

$$\begin{aligned} MFF\phi\phi = & ((RH\phi CD\phi * G * ZCD - G * ZDE\phi * ((RH\phi DD\phi \\ & + RH\phi EE\phi) / 2. \phi) - G * ZEF\phi * RH\phi EE\phi * \\ & RGRAVE) / ((FC\phi * LCD / DCD + ENTRCD + \\ & BENDCD + EXITCD) / (2. \phi * ACD * * 2. \phi \\ & * RH\phi CD\phi) + ((RH\phi EE\phi - RH\phi DD\phi) / \\ & (RH\phi EE\phi * RH\phi DD\phi * ADF * * 2. \phi)) + \\ & (4. \phi * FDE * LDE\phi * 2. \phi) / (2. \phi * DDF \\ & * (RH\phi EE\phi + RH\phi DD\phi) * ADF * * 2. \phi) + \\ & RACLE / (RH\phi EE\phi * ADF * * 2. \phi) + (4. \phi \\ & * FEF * LEF\phi * RFRICE) / (2. \phi * DDF \\ & * RH\phi EE\phi * ADF * * 2. \phi))) * * \phi.5 \quad [IC] \end{aligned}$$

$$\begin{aligned}
 MLL\phi\phi = & ((RHOSH\phi * G * ZGH - G * ZJK\phi * ((RHOJJ\phi \\
 & + RHOKK\phi / 2.\phi) - G * ZKL\phi * RHOKK\phi * \\
 & RGRAVK) / ((FGH * LGH / DGH + ENTGSH + \\
 & BENOGH + EXITGH) / (2.\phi * AGH * * 2.\phi \\
 & * RHOSH\phi + (RHOKK\phi - RHOJJ\phi) / \\
 & (RHOKK\phi * RHOJJ\phi * AJL * * 2.\phi)) + \\
 & (4.\phi * FJK * LJK\phi * 2.\phi) / (2.\phi * OJL \\
 & * (RHOKK\phi + RHOJJ\phi) * AJL * * 2.\phi) + \\
 & RACLJ / (RHOKK\phi * AJL * * 2.\phi) + (4.\phi \\
 & * FKL * LKL\phi * RFRICK) / (2.\phi * OJK \\
 & * RHOKK\phi * AJL * * 2.\phi))) * * \phi.5 \quad [IC]
 \end{aligned}$$

#### 4. Riser Continuity

The relationship between the riser inlet and outlet mass flow rates is written in terms of the continuity equation for one dimensional unsteady flow,

$$\sum_{cs} \rho \bar{V} \cdot \bar{A} = - \frac{d}{dt} \int_{cv} \rho dV$$

In model notation, this becomes

$$MLL = MJJ - DRHOJL * VOLJL \quad [ME]$$

$$MFF = MOD - DRHODF * VOLDF \quad [ME]$$

The numerical differentiation technique used by CSMP-III is highly suspect, as are other techniques. An "averaging" system is used in the actual dynamic model. In addition, the flow rate down the downcomer and into the riser is held constant for the open loop boiler model.

## 5. Riser Quality and Density

The average density in the risers must be solved for explicitly. Linearly varying quality along the riser tube length follows directly from the assumption of uniform heat flux along the riser tube length. The average density along the tube length is the sum of the total change in density and the density entering divided by the riser tube length [1]. Assuming the density varies only in the boiling length of the riser, the total change in density can be written;

$$\int_{\text{boiling length}} \rho(l) dl$$

The average density is

$$\rho_{\text{average}} = \frac{1}{L} \left[ \int_{\text{boiling length}} \rho(l) dl + \rho_f * \text{nonboiling length} \right]$$

where  $\rho_f$  = density of saturated water  
 $L$  = total tube length

Since  $\rho(l)$  varies linearly from entering to exiting,  $\rho(l)$  can be written in the form

$$\rho(l) = \frac{1}{V_f + \frac{X_{\text{out}}}{L_B} (l - L_{NB}) V_{fg}} \quad [1]$$

where  $V_f$  = specific volume entering  
 $X_{\text{out}}$  = quality at riser outlet

$L_B$  = boiling length

$LN_B$  = nonboiling length

$V_{fg}$  = change in specific volume from saturated liquid to saturated vapor

The integral of the explicit equation for  $\rho(l)$  may be solved after rearrangement to

$$g(l) = \frac{1}{\left(V_f - \frac{x_{out} LN_B V_{fg}}{L_B}\right) + \frac{x_{out} V_{fg}}{L_B} l}$$

which is of the form

$$\frac{1}{a + bl}$$

This yields the average density,

$$\rho_{av} = \frac{1}{L} \left[ \frac{L_B}{x_{out} V_{fg}} \ln \left[ \frac{x_{out} V_{fg}}{V_f} + 1 \right] + \rho_f LN_B \right]$$

In model notation the formula is written

$$\begin{aligned} RHO_{DF} &= (1.\phi / L_{DF}) * (L_{EF} \phi / ((X_{FF} \phi) * V_{FG}) \\ &\quad * ALOG (((X_{FF} \phi) / V_F) * V_{FG} + 1.\phi) \\ &\quad + RHO_{DD} \phi * L_{DE} \phi) \quad [IC, ME] \end{aligned}$$

$$\begin{aligned} RHO_{TL} &= (1.\phi / L_{TL}) * (L_{KL} \phi / ((X_{LL} \phi) * V_{FG}) * \\ &\quad ALOG ((X_{LL} \phi * V_{FG}) / V_F + 1.\phi) + RHO_{JT} \phi \\ &\quad * L_{TK} \phi \quad [IC, ME] \end{aligned}$$

To permit calculation of the quality term the energy balance on the liquid in the riser tubes is evaluated. Thus,

$$\begin{aligned} \text{rate of change of riser energy} &= \text{flow energy in} - \text{flow energy out} \\ &+ \text{thermal energy in} \end{aligned}$$

$$\frac{d}{dt} (\rho h V) = \dot{m}_{in} h_{in} - \dot{m}_{out} h_{out} + \dot{q}_{in}$$

If the enthalpy term is treated as the average enthalpy in the riser the equation may be written

$$\frac{d}{dt} (\rho (h_f + x_{out} * h_{fg} / 2) V) = \dot{m}_{in} h_{in} - \dot{m}_{out} h_{out} + \dot{q}_{in}$$

In model notation this is written in the form:

$$DHXLL = (MGG * (HJJ - HF - XLL * HFG / 2.0) + Q6 - MLL * XLL * HFG / 2.0) / (RHOJL * VOLKL) \quad [ME]$$

$$HXLL = \text{INTGRL}(HXLL0, DHXLL) \quad [ME]$$

$$XLL = (HXLL - HF) * 2.0 / HFG \quad [ME]$$

$$DHXFF = (MCC * (HDD - HF - XFF * HFG / 2.0) + Q2 - MFF * XFF * HFG / 2.0) / (RHODF * VOLEF) \quad [ME]$$

$$HXFF = \text{INTGRL}(HXFF0, DHXFF) \quad [ME]$$

$$XFF = (HXFF - HF) * 2.0 / HFG \quad [ME]$$

The initial conditions, HXLLO and HXFFO are calculated in the initial condition program.

The steady state equations for quality are derived differently. The energy transfer rate to the riser liquid may be written in the form

$$\dot{Q} = \dot{m} \Delta h$$

where

$$\begin{aligned}\Delta h &= h_{out} - h_{in} \\ &= h_f + x_{out} h_{fg} - h_{in}\end{aligned}$$

Solving for  $X_{out}$  yields

$$x_{out} = (\dot{Q} + \dot{m} (h_f - h_{in})) / (\dot{m} h_{fg})$$

or

$$X_{FF\phi} = (Q_{1\phi} + M_{FF\phi} * (H_F - H_{DD\phi})) / (M_{FF\phi} * H_{FG}) \quad [IC]$$

$$X_{LL\phi} = (Q_{5\phi} + M_{LL\phi} * (H_F - H_{JJ\phi})) / (M_{LL\phi} * H_{FG}) \quad [IC]$$

## 6. Riser Boiling Boundary Location

The nonboiling length of riser tube is the product of the riser tube length and sensible to total heat ratio [1]

$$L_{NB} = L \cdot q_s / q_t$$

The sensible to total heat ratio may be expressed as the enthalpy change in raising the water to saturated conditions divided by the total enthalpy change, i.e.

$$\frac{q_s}{q_t} = \frac{h_f - h_{in}}{(h_f + x_{out} h_{fg}) - h_{in}}$$

The equations for nonboiling length are

$$L_{OE\phi} = L_{DF} * A_{MAX1}((H_F - H_{DD\phi}), \phi.\phi) / ((H_{DD\phi} + X_{FF\phi} * H_{FG}) - H_{DD\phi}) \quad [IC]$$

$$L_{JK\phi} = L_{JL} * A_{MAX1}((H_F - H_{JJ\phi}), \phi.\phi) / ((H_{JJ\phi} + X_{LL\phi} * H_{FG}) - H_{JJ\phi}) \quad [IC]$$

The Fortran function AMAX1 is used here because the above equations are used in an iterative loop in the initial condition program and there is a possibility during iterations of reaching a situation where the enthalpy entering is greater than saturation enthalpy. The final initial condition solution prevents this. The AMAX1 function is not used for the dynamic model. Thus,

$$LDE = LDF * (HF - HDO) / ((HF + XFF * HFG) - HDO) \text{ [ME]}$$

$$LJK = LJL * (HF - HJJ) / ((HF + XLL * HFG) - HJJ) \text{ [ME]}$$

The boiling volume is derived directly from the solution for the nonboiling length.

$$\text{boiling volume} = \text{total volume} * \frac{\text{boiling length}}{\text{total length}} \quad \text{Hence,}$$

$$VOLEF = VOLDF * LEF/LDF \quad \text{[ME]}$$

$$VOLKL = VOLJL * LKL/LJL \quad \text{[ME]}$$

## 7. Steam Drum Liquid Mass and Energy Balance

The rate of change of liquid mass within the drum is equal to the sum of the mass flow rates entering and leaving the drum. The liquid mass flowing into the drum is the saturated liquid from the risers, the liquid from steam condensation in the drum, and the incoming feedwater. The liquid leaving is that leaving via the downcomers. The dynamic model equation is

$$\begin{aligned} \text{DOMASL} = & \text{MLL} * (1.\phi - \text{XLL}) + \text{MFF} * (1.\phi - \text{XFF}) \\ & + \text{MCOND} + \text{MBB} - \text{MCC} - \text{MGG} \quad [\text{ME}] \end{aligned}$$

The instantaneous mass of liquid in the drum is

$$\text{DMASL} = \text{INTGRL}(\text{DMASL}\phi, \text{DOMASL}) \quad [\text{ME}]$$

where

$$\text{DMASL}\phi = (\text{VOLDRM} * \text{RODRML}) / 2.\phi \quad [\text{IC}]$$

The drum energy balance is derived similarly, i.e.,

$$\begin{aligned} \text{DDMOHL} = & \text{MLL} * (1.\phi - \text{XLL}) * \text{HF} + \text{MFF} * (1.\phi - \text{XFF}) \\ & * \text{HF} + \text{MCOND} * \text{HFG} + \text{MBB} * \text{HBB} - \text{MCC} \\ & * \text{HCC} - \text{MGG} * \text{HGG} \quad [\text{ME}] \end{aligned}$$

The instantaneous drum energy is

$$\text{DMOHL} = \text{INTGRL}(\text{DMOHL}\phi, \text{DMOHL}) \quad [\text{ME}]$$

The initial drum energy is the product of the initial drum liquid mass and initial drum enthalpy.

$$\text{DMOHL}\phi = \text{DMASL}\phi * \text{HDRUM}\phi \quad [\text{IC}]$$

The initial drum liquid enthalpy is

$$\text{DH} = \text{DMOHL} / \text{DMASL}$$

In the dynamic model, drum liquid enthalpy is considered the enthalpy of saturated liquid.

The steam condensation rate equation is based on the difference between the pressure and temperature of the steam and that of the liquid [12]

$$M_{COND} = 56 \phi.93 * (P_{MM} / (T_{MM} + 46 \phi.\phi)) * * \phi.5 - P_{SAT} / (T_{SAT} + 46 \phi.\phi) * * \phi.5) + .\phi2568 \quad [ME]$$

The water level in a marine boiler is generally considered in reference to a mid-drum zero, that is, a water level of plus one inch implies the water level is one inch above the drum centerline. For computational efficiency the assumption is made that for small changes in water level around the midpoint of the drum the water surface area remains constant. This allows a simplified level equation, i.e.,

$$LEVEL = (DMOV - VOLORM / 2.\phi) / (LSTMOM * OSTMOM) \quad [ME]$$

DMOV is the equation for the total volume of "liquid" in the drum. Recalling that a small percentage of steam leaving the separators is entrained in the liquid, the rate equation for "liquid" volume in the drum is

$$DDMOV = ((MFF + MLL - MBB) * VF + PCU * (MLL + mFF) * VV + MBB * VBB - (MCC + MGG) * VF + MCOND * VFG) \quad [ME]$$

where DMDVO is the volume occupied at time zero which is half the drum volume.

#### 8. Circulation System Initial Condition Iteration Procedure

The initial conditions for the circulation system are found by flow rate balancing in the downcomer-riser flow loops. An initial guess of flow rate is made using the assumed riser exit quality of .05 percent which is reasonable for this type of boiler [7]. Coupling this assumption with the assumption that the percent carryunder is zero, an initial approximation of the flow rate can be determined using the figures for initial heat transfer rate to the risers calculated in Section III-A. Hence,

$$\text{mass flow rate} = \frac{\text{heat transfer rate}}{\text{assumed quality} * \text{latent heat of vaporization}}$$

A first approximation of downcomer enthalpy for both banks can be calculated. This downcomer enthalpy is assumed to be the same for all downcomers. Using an energy balance on the liquid in the steam drum

$$MFF\phi = Q1\phi / (XASUME * HFG) \quad [IC]$$

$$MLL\phi = Q5\phi / (XASUME * HFG) \quad [IC]$$

$$HCD\phi = ((MFF\phi + MLL\phi - MBB\phi) * HF + MBB\phi * HBB\phi) / (MFF\phi + MLL\phi) \quad [IC]$$

$$HGH\phi = HCD\phi \quad [IC]$$

The screen riser inlet enthalpy is assumed to be equal to that of the screen downcomer; however the main bank fluid absorbs additional energy from the desuperheater located in that circuit. Therefore, the main bank riser inlet enthalpy

must be calculated separately. Thus,

$$HJJ\phi = HGH\phi + Q9\phi / MHH\phi \quad [IC]$$

The downcomer density must be calculated for use in the pressure drop calculations. Hence,

$$VCD\phi = \frac{((MFF\phi + MLL\phi - MB\phi) * VF + MB\phi * VBB\phi)}{(MFF\phi + MLL\phi)} \quad [IC]$$

$$RHOC\phi = 1.\phi / VCD\phi \quad [IC]$$

$$RHOGH\phi = RHOC\phi \quad [IC]$$

The riser outlet quality is calculated using the initial quality formulation previously developed. This computation is followed by the calculation of the riser non-boiling and boiling lengths.

The average density of the risers is calculated along with the two phase flow multiplication factors for use in the flow rate/pressure drop calculation.

An updated flow rate is now computed and compared with the first approximation. If it is within a specified error criteria calculation stops. If not the previous approximation is updated and the calculations continued with the new approximation.

Upon completion of the flow rate balancing the initial flow rates in the downcomer/riser loops are known along with the riser outlet quality.

The steady state drum specific volume and density are computed as

$$VDRML\phi = VCD\phi + PCU * VV$$

$$RODRML = 1.\phi / VDRML\phi$$

The initial steam mass in the drum is then calculated as

$$OSTM\phi = VOLORM * RHOV / 2.\phi$$

#### 9. Superheater Pressure Drop

All entrance, head, and exit losses are considered negligible in the superheater compared to the frictional pressure drop.

$$\Delta P = f \frac{L}{D} \frac{\dot{m}^2}{A^2 g_{average}}$$

By lumping the constants the pressure drop equation is

$$PMM - PNN = KON1 * mmm * * 2.\phi / RHOMN\phi$$

The following definitions apply here:

$$KON3 = (PMM\phi + PNN\phi) / (RHOMM\phi + RHONN\phi) \quad [IC]$$

$$RHOMN\phi = (RHOMM\phi + RHONN\phi) / 2.\phi$$

$$KON1 = ((PMM\phi - PNN\phi) * RHOMN\phi) / mmm\phi * * 2 \quad [IC]$$

#### 10. Steam Valve Equation

The flow through the steam valve is considered directly proportional to the outlet pressure and valve opening, i.e.,

$$\dot{m} = C * P * (\text{Valve Opening})$$

$$mmm_{III} = PNN * KON4 * VALVE \quad [ME]$$

The constant is computed in the initial condition program.

$$KON4 = mmm_{III} / (VALVE\phi * PNN\phi) \quad [IC]$$

#### E. EQUATIONS OF STATE

The equations of state listed below are used in both the initial condition and dynamic programs. With the exception of the subcooled specific volume equation used for the feedwater entering the drum, they are reasonably accurate in the 300-1500 psi range. The subcooled specific volume equation is accurate in the 600-800 psi range.

$$PSAT = EXP((ALOG(HSAT) - 4.467\phi 8) / .26452) \quad [2]$$

$$TSAT = EXP((.22151 * ALOG(PSAT) + 4.77123)) \quad [2]$$

$$HSAT = EXP(\phi .26452 * ALOG(PSAT) + 4.467\phi 8) \quad [2]$$

$$HFG = 922.15 - \phi .4\phi 516 * PSAT + 1.717E-\phi 4 \\ * PSAT * * 2.\phi - 4.219E-\phi 8 * * 3.\phi \quad [2]$$

$$RHOF = 63.8 - \phi .\phi 1781 * TSAT + 1.132E-\phi 5 \\ * TSAT * * 2.\phi - 6.786E-\phi 8 * TSAT \\ * * 3.\phi \quad [2]$$

$$VBB = .\phi 16\phi \phi 488 - .\phi \phi \phi \phi \phi 2\phi 146 * TBB \\ + 3.6511E-\phi 8 * TBB * * 2.\phi \\ - 8.142E-11 * TBB * * 3.\phi + 1.4\phi 81E-13 \\ * TBB * * 4.\phi - 1.148E-16 * TBB * * 5.\phi \\ + 8.034E-2\phi * TBB * * 6.\phi$$

#### IV. RESULTS AND CONCLUSIONS

##### A. GENERAL

A listing of the initial condition program and the dynamic boiler model program is given in Appendices A and B respectively. The initial condition program output data must be properly formatted for input to the CSMP-III dynamic model. In addition, because the dynamic model utilizes the liquid in the steam drum as a saturation state point from which all other state points are derived, two of the initial conditions must be modified to eliminate a discontinuity between the steady state program and the dynamic model. The equations involved and an explanation are given below.

$DMASL\phi = (VOLDRM * RHOC\phi) / 2.\phi$	[IC]
$DMDHL\phi = DMASL\phi * HORUM\phi$	[IC]
$DMDHL = INTGRL(DMDHL\phi, DDMOHL)$	[ME]
$DMASL = INTGRL(DMASL\phi, DDMASL)$	[ME]
$DH = DMDHL / DMASL$	[ME]

As stated previously, the enthalpy of the liquid in the drum is considered saturation enthalpy. The dynamic model must begin with the rate of condensation in the drum (MCOND) as close to zero as possible. This is a natural steady state position - drum liquid and drum steam both at the same pressure and temperature. In order to insure this to be the case DMASL0 and/or DMDHL0 must be modified such that the initial

drum enthalpy (DH) very closely approximates the enthalpy of saturated liquid corresponding to the drum steam temperature and pressure (PMM and TMM). This is easily facilitated by the use of the CALL DEBUG statement in the dynamic program. With this procedure:

1. The initial condition program is executed and the initial conditions formatted for CSMP-III use.
2. The dynamic model is executed for only a short run time, i.e. 5 seconds.
3. Observing the DEBUG output from the model, DMASLO and/or DMDHLO are modified such that PSAT and TSAT equal PMM and TMM.
4. The model is reexecuted for a short run to check, MCOND should be very small.
5. Since DH is implicitly related to PMM and TMM, the procedure may have to be repeated a few times. The objective is to force as many of the "DERIVATIVE" terms in the DEBUG output to comparatively small figures as possible.

The model as used operates satisfactorily with DMASLO = 8002.2 and DMDHLO = 3.96163E 06. This forces the initial MCOND term to .35949.

Because of the CSMP function DERIV used in the program, the model is extremely sensitive to integration time step. Numerical differentiation is not a desirable function to perform in a dynamic model; however attempts to explicitly differentiate the equations concerned failed. One solution

to the problem is to "smooth" the derivative function by averaging it over several timesteps. The model performed satisfactorily with a fixed-step integration procedure (Runge-Kutta), an integration time step of .04 seconds, and averaging the derivative over sixteen time steps.

## B. OPEN LOOP RESPONSE

The open loop response to a ten percent increase in throttle opening is shown in Figures 2-7. As expected, the response of the main bank circulation loop and screen bank circulation loop is different. This is in keeping with the different purposes of those two loops, steam generation and furnace screening respectively. The effect of the valve opening increase is barely noticeable in the screen circulation loop.

The swell effect is not noticeable. Further conversations with Mr. Paul Weitzel at Babcock and Wilcox indicate that the percentage of "carry under" is not a constant as it was treated in this program. One to two percent is a good starting estimate for steady state; however during a transient "carry under" mass flow rate is computed by subtracting the amount of steam leaving the boiler from the amount of steam produced. This should always be a positive number. The vapor that does not leave the boiler is "carried under." The following program will implement this "carry under":

Modify  
the section of the dynamic  
model titled "COMPUTE THE  
DRUM SPECIFIC VOLUME" to  
read:

```

PROCEDURE CRYUND=FILTR8(MMM)
IF(TIME.GT.0.0)GO TO 45
CRYUND=PCU*(MLL+MFF)
GO TO 46
45  CRYUND=(MLL*XLL+MFF*XFF)-MMM
46  RISE1=DELAY (250,RISTIM,CRYUND)
    RISE2=CRYUND
    IF(VALUE.GT..51)GO TO 55
    RISE=RISE2
    GO TO 57
55  RISE=RISE1
57  CONTINUE
ENDPROCEDURE
DDMDV=((MFF+MLL-MBB)*VF+CRYUND*VV...
      +MBB0*VBB-(MCC+MGG)*VF+MCOND...
      *VFG-RISE*VV)

```

Follow the above statements with the unmodified  
equations for DMDV.

The previous procedure was not implemented in the present  
dynamic model. The quality formulation in the present model  
is apparently too simplified and this causes a shortfall in  
quality at the outlet of the screen riser bank. As a result of  
this shortfall, there are instances during transient operation  
when the model is not "producing" as much steam as it is "using".  
Mr. Weitzel suggests using twenty node finite difference  
approximation for quality. This could be done using an equation  
for quality such as:

$$X = \frac{q}{A g_f V_{in} h_{fg}} Z$$

where

X = quality

Z = distance up the riser (ft)

$q$  = heat input to riser (BTU/s-ft)

$A$  = cross sectional area of riser (ft<sup>2</sup>)

$\rho_f$  = density of saturated liquid (lbm/ft<sup>3</sup>)

$V_{in}$  = velocity of liquid entering (ft/s)

$h_{fg}$  = latent heat of vaporization (BTU/lbm)

Simultaneously an implicit equation for continuity could be applied to produce a balanced mass flow rate without assuming that the downcomer mass flow rate remains constant.

### C. CONCLUSIONS

The model presented is not a finished model. Further research is needed to successfully implement the shrink and swell theories presented. When the previously mentioned difficulty with riser outlet quality is solved, the model should approximate the dynamics of a wide range of D-type marine boilers depending on the initial conditions supplied to the initial condition program.

The initial condition program develops the initial conditions necessary for the detailed boiler model with the relatively scant data available from the boiler technical manual shown in Appendix C and a small amount of data from common engineering handbooks. Because of the relatively small amount of data required the initial condition program and/or the model can serve as a basis for a boiler condition monitoring system.

#### D. SUGGESTIONS FOR FURTHER RESEARCH

It is evident that the model suffers by using the CSMP-III function DERIV. In order to facilitate the explicit solution of the continuity equation for the riser banks some form of differentiation is required, either numerical or explicit. An explicit solution is much more desirable from a stability standpoint. A more detailed investigation with fewer assumptions might produce the correct form for the explicit differentiation equation. It should be noted, however, that when using explicit differentiation the model must average the derivative over at least two time steps to avoid the creation of an algebraic loop. This is easily done with the same PROCEDURE format used to average the derivative in the current model.

The use of small perturbation techniques to linearize the model and thus allow a state-space representation for multi-variable control development and analysis should be undertaken. There is a computer code available locally to facilitate this for CSMP models; however it does not accept the CSMP DERIV function and/or the averaging procedure. A means of bypassing this problem would result in a general D-type boiler model - applicable to a very wide range of boilers currently in use - which could be linearized about specific operating points. These individual models could then be used for the development and testing of multivariable control systems.

Using locally available optimizing computer codes, an optimal D-type boiler design could be attempted with regards to boiler geometry.

A more detailed analytical and experimental investigation of current D-type marine boilers should be undertaken locally. Little research has been done in this area and that which has been done has often been based on either an incorrect physical model of a marine boiler or on a nuclear steam generating plant. A starting point could be the data analysis of common horizontal and vertical steam separators followed by an optimum design for these elements. The improper and/or maintenance of drum internals apparently grossly affects boiler operation and water level stability during rapid transients.

TABLE 1  
MODEL NOTATION

PRINCIPAL LETTER OR ACRONYM	MEANING	EXAMPLES
T	TEMPERATURE	TAA - temperature of fluid entering the economizer TAB - average temperature of fluid in the economizer TAAO - initial temperature of fluid entering the economizer
H	ENTHALPY	HDD - enthalpy of liquid entering the screen riser HDDO - enthalpy of liquid entering the screen riser at time zero
V	SPECIFIC VOLUME	VBB - specific volume of liquid at economizer outlet
X	QUALITY	XFF - quality at outlet of screen risers XLL - quality at outlet of main bank risers DXFF - time rate of change screen riser outlet quality
RHO	DENSITY	RHODD - density at outlet of screen downcomer RH OCD - average density in screen downcomer
M	MASS FLOW RATE	MGG - mass flow rate down main bank downcomer MRRO - mass flow rate of flue gas through the superheater at time zero
Q	ENERGY TRANSFER	Q1 - energy transfer from furnace flue gas to screen riser tube metal Q2 - energy transfer from screen riser tube metal to screen riser fluid

NOTE: In general, rate variables  $\frac{d}{dt}$  are preceded by the letter D, i.e., DXFF, DRHOJL.

$RHCFFO = (1.0 / LDF) * (LEFO / ((XFFO * VFG) * \text{ALOG}(((XFFO * VFG) / V) * VFG + 1.0)) + RHCCDO * LDEO)$

CALCULATE THE AVERAGE DENSITY IN THE MAIN BANK RISER

$RHCJLO = (1.0 / LJL) * (LKLO / ((XLLO * VFG) * \text{ALOG}(((XLLO * VFG) / V) * VFG + 1.0)) + RHCCJO * LJKO)$

CALCULATE THE EFFECTIVE HEIGHT OF THE RISERS

$ZDEO = ZDF - LEFO$   
 $ZJKO = ZJL - LKLO$   
 $ZEFO = ZDF - ZDEO$   
 $ZKLO = ZJL - ZJKO$

COMPUTE THE TWO PHASE FLOW MULTIPLICATION FACTORS

$RGRAVE = 24.794 * XFFO ** 2.0 - 6.5066 * XFFO + .9776$   
 $RGRAVK = 24.794 * XLLO ** 2.0 - 6.5066 * XLLO + .9776$   
 $RACLE = 15.4564 * XFFO ** 2.0 + 13.4944 * XFFO - .00007$   
 $RACLJ = 15.4564 * XLLO ** 2.0 + 13.4944 * XLLO - .00007$   
 $RFRICE = -34.0822 * XFFO ** 2.0 + 23.7164 * XFFO + .8734$   
 $RFRICK = -34.0822 * XLLO ** 2.0 + 23.7164 * XLLO + .8734$

CALCULATE SECOND APPROXIMATION OF MASS FLOW RATE AT EXIT OF SCREEN RISERS

$RHOEE0 = RHODDO$   
 $MFFCC = ((RHCCDO * G * ZDC - G * ZDEO * ((RHODDO + RHOEE0) / 2.0)) - G * ZEFO * RHOEE0 * RGRAVE) / ((FCO * LCO / DCJ + ENTRCO) + BENICC * EXITCO) / ((2.0 * AGH ** 2.0 * RHODDO) + ((PHIEEO - RHODDO) * ((RHODDO * RHCCDO * ADF ** 2.0) + (4.0 * FDE * LDEO * 2.0) - 8) / ((2.0 * DDF * (PHIEEO - RHODDO) * ADF ** 2.0) + RACLE / 8) * ((RHCEEO * ADF ** 2.0) + (4.0 * FEF * LEFO * 2.0 * FFRICE) / 8) * ((2.0 * DDF * RHOEE0 * ADF ** 2.0) + 8) * 0.5$

CALCULATE SECOND APPROXIMATION OF MASS FLOW RATE AT EXIT OF MAIN BANK RISERS

$RHOKKO = RHOUJO$   
 $MLLOO = ((RHUGHO * G * ZGH - G * ZJKO * ((RHOUJO + RHOKKO) / 2.0)) - G * ZKLO * RHOKKO * RGRAVK) / ((FCF * LCF / DGH + EITPGH) + BENOGH * EXITGH) / ((2.0 * AGH ** 2.0 * RHUGHO) + ((RHOKKO - RHOUJO) * ((RHOUJO * RHUGHO * ADF ** 2.0) + (4.0 * FJK * LJL * 2.0) - 8) / ((2.0 * DJL * (RHOKKO + RHOUJO) * ADF ** 2.0) + RACLJ / 8) * 0.5$

# APPENDIX C

## G. Anticipated Performance

	Endurance 2 Boilers	Design Rated Full Power	Maximum Intermittent Power	Endurance 1 Boiler	Boiler Overload
Rate of Operation - Per Cent	56	83	97	114	120
Total Steam Generated lb/hr	195,000	290,000	340,000	400,000	420,000
Superheated Steam lbs/hr.	155,000	235,000	265,000	300,000	320,000
Deaerated Steam lbs/hr.	40,000	55,000	75,000	100,000	100,000
Boiler Drum Pressure psig	690	690	690	690	690
Superheater Outlet Pressure psig	665	630	610	580	570
Superheater Outlet Temperature °F	912	914	980	898	895
Deaerated Steam Outlet Pressure psig	651	606	558	480	470
Deaerated Steam Outlet Temperature °F	635	659	680	690	690
Economizer Inlet Pressure psig	715	726	733	749	754
Economizer Inlet Temperature °F	250	250	250	250	250
Economizer Outlet Pressure psig	703	705	703	708	710
Economizer Outlet Temperature °F	355	372	372	377	380
Casing Air Inlet Temperature °F	100	100	100	100	100
Total Air Flow lb/hr	242,229	368,092	433,589	513,154	540,952
Total Oil Flow lb/hr	14,333	21,781	25,656	30,364	32,009
Anticipated Efficiency %	85.7	84.4	83.8	83.0	82.7
Guaranteed Efficiency %	85.7	84.4	83.8	83.0	82.7
Radiation and Unaccounted for Losses %	.99	.99	.95	1.01	.98
Excess Air %	15.0	15.0	15.0	15.0	15.0
Carbon Dioxide %	13.0	13.0	13.0	13.0	13.0
Number of Burners in Operation	6	6	6	6	6
Throttle or Non-Throttle of Air Doors	N.T.	N.T.	N.T.	N.T.	N.T.
Drain Loss - Total Inches Water	13.74	33.98*	47.96	69.51	76.22** 93.48***
Through Double Casing	1.33	3.09	4.28	6.00	6.67 10.22
Through Burner Register	2.60	6.00	8.50	11.50	13.00 15.88
Through Boiler & Superheater	4.83	12.29	18.14	25.61	28.15 38.32
Through Economizer	4.98	12.60	17.04	26.40	28.40 29.06
Gas Temperature Leaving Superheater Screen °F	2471	2594	2642	2686	2699
Gas Temperature Leaving Superheater °F	1826	1961	2021	2085	2103
Gas Temperature Leaving Main Bank °F	694	774	812	856	872
Gas Temperature Leaving Economizer °F	373	427	453	484	498
Heat Release KB/Hr/Sq. Ft. Radiant Heat Absorbing Surface	447	680	800.6	948	999
Heat Release KB/Hr/Sq. Ft. Total Heating Surface	15.5	23.6	28.0	32.9	34.7
Heat Release KB/Hr/Cu. Ft. Furnace Volume	183.9	279.5	329.2	389.6	410.8
Furnace Heat Absorption KB/Hr/Sq. Ft.	128.4	171.0	191.1	213.19	221.5
Heat Absorption First Water Screen Row KB/Hr/Sq. Ft. (Max.)	210	231	255.3	288	256
Heat Absorption Maximum KB/Hr/Sq. Ft. (Furnace Screen)	210	231	255.3	288	256

Drain Losses (Full Power) Based On 241 Cu. Ft. of 100°F Air/Lb. of Fuel Oil

\*Drain Losses (Overload) Based On 241 Cu. Ft. of 100°F Air/Lb. of Fuel Oil

\*\*Drain Losses (Overload) Based on 260 Cu. Ft. of 68°F Air/Lb. of Fuel Oil

## II. Anticipated Metal Temperature Degree F.

	Endurance 2 Boilers	Design Rated Full Power	Maximum Intermittent Power	Endurance 1 Boiler	Boiler Overload
Water Screen Tubes Outside	644	656	661	667	680
Water Screen Tubes Inside	554	554	554	554	555
Superheater Tubes Outside - Maximum	1022	1046	1049	1048	1048
Superheater Tubes Inside - Maximum	1044	1020	1019	1014	1012
Maximum Inner Casing Temperature	800	825	835	850	870
Maximum Outer Casing Temperature at way of Structural ties	350	350	350	350	350
Maximum Outer Casing Temperature	145	145	145	145	145

### Tube Data

	O.D.	M.W.T.	No.	Material
Side Wall and Roof	2"	.134"	71	MIL-T-16286 CL. A*
Rear Wall	2"	.134"	54	MIL-T-16286 CL. A*
Front Wall	2"	.134"	22	MIL-T-16286 CL. A*
